The milkfish hatchery

By M Castaños

Yes, it is quite profitable for hatchery owners to convert their tiger shrimp hatchery to milkfish hatchery.

A newly released report* from SEAFDEC/AQD assessed the economic viability of 4 commercial milkfish hatcheries operating in 1992. AQD researcher Dr. Luis M. Garcia notes that hatchery owners can get a 54-61% return-on-investment and about 1.5 years payback period from operating either a large- or small-scale hatchery. The hatchery is operated using the technology developed by AQD in the '80s.

The conditions of profitability are as follows:

- the eggs or newly-hatched larvae are acquired at P6,000 per million at most**
- the selling price of fry is P0.50 each, if not more

**Presently, only SEAFDEC/AQD sells, if not gives out for free, milkfish eggs or newly hatched larvae to private hatcheries under its Accelerated Transfer of Milkfish Hatchery Technology Program. For inquiries about this program, contact <aqdchief@aqd.seafdec.org.ph>.

The 4 hatcheries that AQD assessed have total tank capacity of 145 to 325 tons, with capital outlay of over P128,000 (small-scale) or P833,000 (large-scale). The capital outlay, Dr. Garcia says, is used for facilities and equipment needed for milkfish operation like additional larval food tanks.

In terms of production, the hatcheries produced half a million to nearly 4 million fry from 3-6 operations conducted from April to October. Larval survival ranged from 15 to 42% after 21-24 days. Earnings from the hatchery were nearly P200,000 to over P1 million.

"Hatchery operators can earn more than double the selling price of its produce by rearing 21-day old fry for an additional two weeks in nursery ponds," suggests Dr. Garcia. "The operational expenses of rearing fry in nursery ponds are minimal, because fry thrive on naturally grown food organisms."

More recently, two more hatchery owners attest to the profitability of milkfish hatchery using AQD technology. Luis Rojas of TRC hatchery (Batan, Aklan) and Salvador Gestosani of Sto. Nino hatchery (Guimbal, Iloilo) made runs starting 1996. But the hatcheries encountered low acceptance of hatchery fry by fishpond owners due to the perceived low growth and high mortalities.

If you're interested to go into the milkfish broodstock business, AQD can provide technical assistance. AQD has a working technology for broodstock management, handling and transport; and as well as the all-important feeding management scheme.

AQD has also a demonstration complex for its fish breeding-hatchery technologies. To arrange visits, contact: <training@aqd.seafdec.org.ph>

However, there are private milkfish pond owners currently raising milkfish broodstock in ponds or tanks who may sell eggs or hatchlings. (One company said it imported 2,500 spawners from Taiwan, and has in stock 13,000 breeders of varying ages out of locally sourced fry. However, only 5,000 of these are described as "productive.") It is best to contact the nearest DA-BFAR office because some of these broodstocks were "privatized" stocks of the now-defunct National Bangus Breeding Program (NBBP).

If you're interested to go into the milkfish broodstock business, AQD can provide technical assistance. AQD has a working technology for broodstock management, handling and transport; and as well as the all-important feeding management scheme.

Training series for fry gatherers

SEAFDEC/AQD is conducting a series of lectures and training among fry gatherers in five southern Iloilo towns about the status of the milkfish fry fishery, the effect of the fry fishery on other fishery resources, and the use of milkfish and some larval by-catch in aquaculture.

These fry gatherers are among the many stakeholders being trained for empowerment under the Panay Gulf Development Program (PGDP) of Congresswoman Ninfa Garin of Iloilo’s First District. The project aims for both economic development in coastal towns and the conservation of coastal marine resources in Panay Gulf.

An AQD trainor emphasized that it is bad practice for milkfish fry gatherers to dump the larval by-catch because these larvae would otherwise grow to be the bigger fish caught by the municipal and commercial fisheries. All the fry gatherers were also fishermen (and some women), and they easily understood that in order for them to have big fish to catch, they must return to sea the larval by-catch from milkfish fry gathering.

The fry gatherers do recognize some of the other species of fish larvae and juveniles, but they had to be taught that snappers, groupers, seabass, rabbitfish, mullets, and scats have a potential market as seed for aquaculture. The PGDP also plans to use some of the freshwater-tolerant larval by-catch to seed upland and inland water bodies.

The lectures and discussions were conducted in the dialect, with plenty of visual aids. The first three batches of fry gatherers (total about 100) came from San Joaquin, and several more batches from Miagao, Guimbal, Tigbauan, and Iloilo will take their turn in the next few months. - By TU Bagarinao

Milkfish fry gatherers. Milkfish fry gatherers of southern Iloilo’s coastal towns are currently training at AQD on the identification, catching, and handling of fish fry other than milkfish. Fry of seabass, siganid, grouper, spotted scat or ‘kikiro’, mullet, among other species are often thrown away because gatherers do not know their aquaculture potential

incidence of deformity in market-sized milkfish. However, with the sporadic scarcity of fry from the wild, pond owners may no longer have a choice (see related story).

Nine other hatcheries are currently cooperating with AQD in testing its hatchery technology.

AQD’s hatchery technology

Operating a milkfish hatchery is not much different from operating a tiger shrimp hatchery. The hatchery operator still needs to maintain good water quality and give

Features on milkfish

We previously run a series on the milkfish industry that appeared in five issues of this newsletter, SEAFDEC Asian Aquaculture. The articles are on:

- Prospects of milkfish sea cage farming
- Industry situationer: milkfish farming in marine pens / cages
- Ecological limits of high-density milkfish systems
- Economic value of the milkfish industry
- Fry supply from the wild
- Broodstock development in the Philippines
- Milkfish ponds from mangroves

Limited copies of back issues are available. Write to: <sales@aqd.seafdec.org.ph> or fax (63-33) 336 2891
the right type of food to the milkfish at the right time and quantity. Larval rearing operations are presented in a chart that a hatchery operator follows, and where the water management, feeding scheme, and other critical procedures are indicated.

The chart on page 14 is AQD's new and improved method of rearing milkfish larvae. It also reflects the actual practice of hatchery operators.

"We are able to improve the nutrition of the larvae by using vitamin C and what we call HUFA or highly unsaturated fatty acids," explains AQD researcher Rolando Gapasin. "Vitamin C works the same in humans as in fishes. It strengthens the bones, reducing the incidence of scoliosis, distorted or twisted Gill filaments, and short operculae and snout. Fatty acids are essential, too. What we are sure of is that, without fatty acids, fish larvae grow poorly, feeding is not very efficient, larvae develop anemia and there is high mortality."

So, in the chart, hatchery owners provide not just rotifers and Artemia, but enriched rotifers and Artemia. Enrichment is done by feeding these rotifers and Artemia HUFA booster diets supplemented with Vitamin C (commercially available) before these are given as feed to milkfish larvae. Enrichment may also be done by feeding rotifers/Artemia with microalgae with high HUFA content.

Better growth is the obvious result, but so is lesser incidence of deformed operculum where the gills are exposed.

The rate of fry deformity does not seem to have a large impact in nursery and grow-out ponds. The DA-BFAR station in Pagbilao, Quezon which made an independent study comparing wild and hatchery fry in nursery pond (~10 weeks) reported that only 3% of hatchery fry can be considered "abnormal," but growth rates are about the same. On the other hand, an AQD cooperater in Negros reported a mere 0.23% deformity after about 9 weeks in nursery pond. Newly hatched larvae were sourced from AQD’s Tigbauan Station, Iloilo so transport stress may help account for the difference in survival.

In actual grow-out culture, deformity can hardly be seen in harvest-sized milkfish. AQD cooperators reported 0.003 to 0.05% aesthetically, visually unappealing fish in their commercial runs using hatchery fry. Wild and hatchery fry probably taste the same.

AQD remains cognizant of the industry's apprehensions regarding hatchery produce. Thus, researchers continue in their efforts to refine the milkfish hatchery technology.
